R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 **Abstract:** In 2000, the Dideron (D) strain of *Plum pox virus* (PPV) was detected in commercial
4
5 2 peach and nectarine orchards in the Niagara region of Ontario where most of Canada's stone
6
7 3 fruit crops are produced. As part of a disease management research program, peach (*Prunus*
8
9 4 *persica* L. Batsch) trees in a commercial orchard at Niagara-on-the-Lake were assayed for PPV
10
11 5 annually for 3 years. The orchard consisted of two blocks of the cultivars 'Allstar' and
12
13 6 'Brighton', of which 4 of 288 and 5 of 252 trees, respectively, were infected with PPV. The
14
15 7 growth and health of these PPV-infected and non-infected trees were evaluated based on the
16
17 8 annual growth rates, vigour (chlorophyll content) and bud winter hardiness. Comparative fruit
18
19 9 quantity and quality index values were based on total yield and marketable yield per tree, fruit
20
21 10 size and weight, fruit pH, titratable acidity, total soluble solids, flesh firmness, and fruit skin
22
23 11 colour. Results from these preliminary studies showed that trees infected with this mild Ontario
24
25 12 isolate of PPV produced slightly more fruit of smaller size that ripened earlier than non-infected
26
27 13 trees. However, yield efficiencies based on weight of fruit relative to the trunk cross sectional
28
29 14 area did not differ statistically. Screenhouse studies on three graft-inoculated fresh market peach
30
31 15 cultivars ('Babygold', 'Catherina', and 'Garnet Beauty') similarly did not demonstrate any
32
33 16 differences in growth or fruit production in the 2nd and 3rd year post inoculation, but fruit on
34
35 17 infected trees matured somewhat earlier.

R. Samara et al. Impact of *Plum pox virus* infection...

1 Introduction

2 Approximately 25,500 tonnes of peaches (*Prunus persica* L. Batsch) with a farm gate value of
3 C\$ 32.6 million are produced in Canada annually (Statistics Canada, 2012). The Niagara
4 region of southern Ontario is the primary production area with over 85% of the total peach
5 acreage.

6 *Plum pox virus* (PPV) is one of the most damaging viral diseases of stone fruit (*Prunus*
7 spp.) worldwide (Nemeth 1986; Cambra et al. 2006; Wijkamp et al. 2011). Different strains of
8 PPV significantly limit production of peaches, plums (*P. domestica* L.), apricots (*P. armeniaca*
9 L.), and other stone fruits in areas where they are established. Economic losses from these
10 strains can be catastrophic to stone fruit production in large geographic areas (Agrios 1990),
11 with estimated losses exceeding €10 billion worldwide (Cambra et al. 2006). Induced
12 symptoms vary depending on the virus strain and host cultivar. Leaves may have pale green
13 spots, lines and rings, vein clearing or yellowing bordering secondary or tertiary veins, leaf
14 puckering, crinkling and curling. Colour breaking may occur in flowers on some cultivars.
15 Infected fruit may have rings, chlorotic spots, blotches, and deformities. Trees may exhibit
16 reduced growth and vigor and be less tolerant to drought and cold (Cambra et al. 2012). The
17 virus is transmitted through infected propagation material and by numerous aphid species in a
18 non-circulative, non-persistent manner (Labonne et al. 1994, 1995; Gildow et al. 2004; ;
19 Lowery et al. 2009, 2015).

20 In 1999, the Dideron strain of PPV (PPV-D) was first detected in North America in
21 several peach and plum orchards in Pennsylvania (Levy et al. 2000; Damsteegt et al. 2001). The
22 following year, PPV was found in nectarine, peach and ornamental *Prunus* spp. in Ontario and in
23 peach in Nova Scotia, Canada (James & Upton 2001; Thompson et al. 2001). An eradication

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 program was implemented between 2000 and 2011 (Gougherty & Nutter 2012; Gottwald et al.
4
5 2 2013; CFIA 2014; Treasury Board of Canada Secretariat 2015). Orchards identified as having
6
7 3 infected trees were partially or fully removed and growers received compensation from a
8
9 4 government program (CFIA 2014). Propagative spread is believed to account for the introduction
10
11 5 and much of the initial dissemination of the virus in Ontario (Gottwald 2006). The D strain of
12
13 6 PPV is generally thought to be not as effectively transmitted by aphids as other strains and tends
14
15 7 to spread more slowly (Brunt et al. 1997; Wijkamp & van der Gaag 2011; Šubr & Glasa 2013).
16
17 8 However, atypical isolates of PPV-D that spread more rapidly within and between peach
18
19 9 orchards have been reported from France (Dallot et al. 1998) and Chile (Herrera 2013). In
20
21 10 Canada, the eradication program was replaced in 2011 with a disease management and
22
23 11 monitoring program that maintained a quarantine zone within a 1.5 km monitored buffer zone.
24
25 12 By 2011 most of the processing peach cultivars (primarily clingstone cultivars) had been
26
27 13 removed, in part because of higher disease incidence and symptomatic fruit, but mostly resulting
28
29 14 from closure in 2008 of the last remaining fruit canning facility in southern Ontario. For this
30
31 15 reason, our research was limited to fresh market freestone cultivars.
32
33
34
35
36

37
38 16 The impact of PPV on fruit production depends on many factors, including the virus
39
40 17 strain and isolate, tree cultivar and age, rootstock, cultural practices, time and mode of infection,
41
42 18 presence of vector species and climatic conditions (Usenik et al. 2014). Little is known about the
43
44 19 impact of the Ontario isolate of PPV-D on peach vigour, fruit production, fruit quality, and
45
46 20 winter hardiness under cool temperate conditions. Further, the Ontario PPV-D strain is different
47
48 21 from other reported PPV-D isolates based on molecular mapping studies (Theilmann et al. 2006;
49
50 22 Maejima et al. 2011; Schneider et al. 2011; James et al. 2015) and transmission efficiency
51
52 23 (Lowery & Vickers 2007; Lowery et al. 2009, 2015). Isolates from the US, Canada and Chile are
53
54
55
56
57
58
59
60

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 believed to be more closely related to each other than to European isolates. The two US isolates
4
5 2 from Pennsylvania were transmitted more efficiently by *M. persicae* than a European D isolate
6
7 3 (Schneider et al. 2011). The first isolates of PPV strain W (isolate W3174) and PPV-Rec
8
9 4 described in *Prunus* in Niagara were discovered on residential properties; neither isolate has
10
11 5 been detected in commercial stone fruit orchards in Canada. These two isolates appear to
12
13 6 represent separate and distinct introductions by homeowners (James and Varga 2005; James et
14
15 7 al. 2015). Increasing levels of PPV inoculum in the industry may be a potential reservoir for
16
17 8 intra-strain variation. PPV strains are characterized by relatively low intra-strain diversity
18
19 9 (reaching 1.1%–3.9% at the nucleotide level for full-length genomes, except for PPV-W, where
20
21 10 the divergence reaches 7.9%) and by comparatively high between-strain diversity (4.4%–22.8%;
22
23 11 Glasa et al. 2012). Although forming monophyletic groups, PPV-M, PPV-D, PPV-Rec, PPV-T
24
25 12 and PPV-W are evolutionarily linked by recombination events, including an ancestral
26
27 13 recombination affecting the 5' part of PPV-M, PPV-D and PPV-Rec strains (Garcia et al. 2014).
28
29 14 Such mutations could alter pathogenicity and host range determinants (Glasa et al. 2012; Garcia
30
31 15 et al. 2014).

32
33 16 The objective of this study was to monitor and assess the effects of the Ontario PPV-D
34
35 17 isolate on two fresh market peach cultivars in an orchard over three consecutive years. We also
36
37 18 examined early infection on newly planted trees and its impact on production and tree viability.
38
39 19 The findings will address some of the controversy in the industry regarding the impact of PPV at
40
41 20 the farm gate and on tree viability.

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 At the termination of the federal PPV eradication program in 2011, it was difficult to locate and
4
5 2 gain access to sites with infected trees. An extensive survey (11,740 trees) was conducted in the
6
7 3 2011-2012 dormant season, with follow up sampling in the 2012 growing season throughout
8
9 4 commercial peach orchards in Niagara, Ontario, with a previous history of PPV infection. Five
10
11 5 trees of PPV-infected cv. 'Brighton' (ca. 4 yr old) and four trees of cv. 'Allstar' (ca. 7 yr old)
12
13 6 were identified in an orchard in Niagara-on-the-Lake. All infected trees of both fresh market
14
15 7 cultivars used in our field study between 2012 and 2015 were uniformly infected with virus
16
17 8 throughout the tree scaffolds. 'Allstar' and 'Brighton' infected with the local isolate of PPV-D
18
19 9 were mildly symptomatic, with faint line patterning. This is similar to group 2 (tolerant cultivars)
20
21 10 defined by Polak et al (2003) for the classification of peach cultivar susceptibility to PPV. Basal
22
23 11 leaves on shoots consistently tested highly positive for PPV by both ELISA and PCR. No
24
25 12 symptoms were present on the fruit. For negative controls, 10 non-infected trees of each cultivar
26
27 13 located randomly throughout the orchards were selected. For each cultivar, trees used in the
28
29 14 study were planted at the same time (cvs 'Allstar' in 2006 and 'Brighton' in 2009) and were
30
31 15 similar in growth and appearance, and free of any obvious diseases such as peach canker. Trees
32
33 16 were spaced 3 m within rows and 4 m between rows and trained to an open centre with three to
34
35 17 five main scaffolds. Cultural management practices and pesticide applications were made
36
37 18 according to standard commercial practices for the area (OMAF 2006). Annually at leaf-out
38
39 19 (April - May), 4 – 5 scaffolds of each study tree were mapped into at least 20 branches per
40
41 20 scaffold, and 12 basal leaves were collected from each branch and stored for no more than 48 h
42
43 21 at 4°C until assayed. Leaves were macerated in ELISA extraction buffer (EEB) (1:6,
44
45 22 tissue:buffer) (Clark & Adams 1977). The suspension was further diluted using Direct Plant
46
47 23 Extraction Buffer (DiPEB) (1:9, macerate in EEB:DiPEB) and assayed by Direct Reverse

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 Transcriptase Real Time Polymerase Chain Reaction Assay (DRT-qPCR) (Kim et al. 2008).

4
5 2 Overall, infection was uniformly distributed in the test trees, suggesting that the trees were not
6
7
8 3 newly infected.

4 ***Screenhouse study***

5 To study the impact of early PPV infection of peach nursery stock on production and viability
6 of trees, a 465 m² screenhouse was modified to containment level 2 standards and certified by
7 the Canadian Food Inspection Agency (CFIA) for PPV studies. Two screened overhead
8 ventilation fans provided air circulation and annual whitewash applications kept temperatures
9 close to ambient levels over most of the growing season. In June 2011, 15 two year old peach
10 trees certified free of PPV of each of three peach cultivars ('Babygold', 'Catherina', 'Garnet
11 Beauty') were planted in a randomized complete block design with 1.7 m x 1.5 m spacing
12 between rows and trees respectively. The screenhouse was maintained free of aphids and
13 monitored by regular inspections and yellow sticky cards. Trees were drip irrigated and
14 maintained according to standard commercial practice. In September 2012, 10 trees of each
15 cultivar were T-bud grafted with 5 PPV-infected buds from infected peach stock. Trees were
16 tested for virus in the spring and summer from 2013-2015. By 2014, 8, 5, and 9 of the
17 inoculated trees of 'Baby Gold', 'Catherina' and 'Garnett Beauty' respectively were PPV
18 infected. Based on Polak's definitions (Polak 2003), 'Catherina' and 'Garnett Beauty' were
19 considered to be in Group 2 (tolerant) and 'Babygold' in Group 3 (medium susceptible cultivar,
20 Polak 2003). These trees and the five uninoculated trees per cultivar were subsequently
21 monitored in 2014 and 2015 for growth, yield and fruit quality as previously described.

22 ***B. Vegetative growth and fruit yield evaluations***

23 ***Field Study***

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 Mature orchard trees were monitored to determine the effects of PPV on tree vigour, growth,
4
5 2 yield, fruit quality and winter bud hardiness. Examinations were made in the field and in the
6
7 3 laboratory at AAFC in Vineland Station, ON. Tree circumferences (30 cm above ground) were
8
9 4 measured early in the growing season each year, and increases in trunk girth calculated for each
10
11 5 year of the three year study period. Trunk cross sectional area (TCSA) was calculated to compare
12
13 6 the vegetative growth of infected and non-infected trees per cultivar (Lepsis & Blanke 2006). At
14
15 7 marketable fruit maturity as determined by the grower and in accordance with provincially-
16
17 8 regulated minimum fruit sizes for fresh market peaches (OTFPMB 2014), fruit was harvested
18
19 9 into separately labeled baskets and weighed to obtain total fruit yield per tree. This required 2-3
20
21 10 picks per cultivar. Fruit was then stored at 4°C and 50-60% RH in a cold storage chamber for 24
22
23 11 h before being assessed for quality.

12 ***Screenhouse study***

13 The young trees were studied similarly to the field trees with the following exceptions. No winter
14
15 14 bud hardiness data were collected, trunk circumferences were measured in mid-August annually
16
17 15 and fruit was harvested and assessed the same day.

16 ***C. Fruit quality assessment***

17 ***Field study***

18 Fruit was first graded using a GREEFA grading machine (A3-UP Greefa®, the Netherlands) into
19
20 19 seven size classes (<57, 57-64, 64-70, 70-76, 76-83, 83-89, >89 mm diameter for cv. Brighton;
21
22 20 two lowest classes for Allstar were <54 and 54-64, the other categories were the same).
23
24 21 Marketable fruit size was based on provincially-regulated minimum fruit sizes for fresh market
25
26 22 peaches (OTFPMB 2014). The minimum fruit size was 57 mm for early-season peaches (e.g.
27
28 23 'Brighton') and ~60 mm for main season peaches (e.g. 'Allstar'). However, because of limited

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 sales opportunities for small size fruit the cooperating grower considered fruit less than 64 mm
4
5 2 unmarketable. Total fruit numbers and total fruit weight for each class were recorded. For each
6
7 3 tree, a sample of 10 market-size peaches per scaffold were chosen for fruit quality assessments,
8
9 4 which included diameter, fruit skin colour, firmness, total soluble solids, juice pH and titratable
10
11 5 acidity. Maximum fruit diameter was measured in two directions using an electronic caliper with
12
13 6 LCD readout (Mastercraft®, 58-6800-4, Canadian Tire). Colorimetric measurements of fruit skin
14
15 7 colour were determined from both sides of each fruit using a Chroma meter CR-400 (Konica
16
17 8 Minolta Sensing Inc., Japan) that measured light reflectance ('L' value) and the intensity of the
18
19 9 red or green ('a' value) and yellow or blue ('b') colours (Voss 1992). The 'C' values measured
20
21 10 the Chroma and the 'h' values measures the hue angle. Fruit firmness was measured using a
22
23 11 digital Fruit Texture Analyser (FTA; GUSS-GS-14®, South Africa) with a 12 mm diameter
24
25 12 stainless steel cylinder probe that was applied to opposite sides of each fruit on an area with the
26
27 13 skin removed to expose the fresh flesh. A fruit and vegetable extractor (Health Smart 67900,
28
29 14 Hamilton Beach®, Picton, ON) was used to obtain juice from a composite of the 10-fruit sample
30
31 15 per scaffold. The extracted juice was collected in 20 ml labelled plastic cups from which two or
32
33 16 three drops were placed on the prism of a digital refractometer (PR-32α, Atago®, Japan; range 0-
34
35 17 32°Brix) for measurements of total soluble solids (TSS). Titratable acidity (TA) of the extracted
36
37 18 juice was measured using a pH meter (Fisher Scientific®, Ottawa, ON). A 7.5 ml aliquot of juice
38
39 19 was then diluted with 92.5 ml de-ionized water and titrated with 0.1 N sodium hydroxide to a pH
40
41 20 8.1 (± 0.2) end point, using the 860 compact Titrosampler, (Metrohm®, Switzerland), and the
42
43 21 volume of NaOH used was recorded as the TA volume.
44
45
46
47
48
49
50

51 **Screenhouse study**

52
53
54
55
56
57
58
59
60

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 Fruit was manually graded with a minimum circumference of 15 cm accepted for the study. This
4
5 2 translates into a minimum diameter of 4.8 cm (circumference $\times 10/\pi$). Peaches were smaller than
6
7 3 those collected from older orchard trees. A total of 20 fruit were taken from each tree and their
8
9 4 quality assessed as described excluding titratable solids measurements.

5 ***D. Foliar chlorophyll content and cold hardiness assessments***

6 ***Field study***

7 Chlorophyll content of leaves of PPV-infected and non-infected trees, which is closely
8 associated with plant nitrogen status, was measured using a SPAD (SPAD-502 plus, Konica
9 Minolta Co., Ltd., Japan) chlorophyll meter that measures the transmission of radiation through
10 the leaf at wavelengths near 650 and 940 nm. During the growing season, an average of three
11 readings per leaf was recorded from six or seven leaves per tree selected as the third or fourth
12 fully expanded leaves from the shoot apex. A total of four PPV-infected and four non-infected
13 trees per cultivar were monitored over three years.

14 As described by Mills et al. (2006), differential thermal analysis (DTA) based on freezing point
15 of water in plant tissues was used to detect the lethal low-temperature exotherm (LTE) for
16 dormant peach flower buds. During the winter, 10-15 pencil-thick (ca. 1 cm diameter) shoots per
17 tree scaffold from both PPV positive and negative trees were collected, labelled, and stored at
18 4°C until processed within a week. The DTA consisted of the thermoelectric modules (TEMs)
19 (model CP1.4-127-045L; Melcor Corporation, Trenton, NJ), the Keithley Multimeter Data
20 Acquisition System (DAS) (model 2700-DAQ-40; Keithley Instruments, Cleveland, OH) and a
21 programmable freezer (Tenney Environmental Test Chamber model T2C, Thermal Product
22 Solutions, Williamsport, PA), and output computer software (Bud LTE 1.2.3; Brock University,
23 St. Catharines, ON). The remaining dormant buds and cambium tissues were macerated and

R. Samara et al. Impact of *Plum pox virus* infection...

1 diluted in EEB and DiPEB as previously described and the tissue suspensions assayed for the
2 presence of PPV by DRT-qPCR.

3 ***Screenhouse study***

4 No SPAD and DTA readings were conducted on the screenhouse trees.

5 ***E. Statistical analyses***

6 Data from each experiment was checked for normality and homogeneity of variance. Where
7 necessary, Box Cox Y transformations, or arcsine square root transformations in the case of
8 proportional data, were applied to the data to satisfy the assumption of normality. All statistical
9 tests were performed using JMP version 10 (SAS Institute Inc., Cary, North Carolina), with all
10 statistical error rates pre-set with an $\alpha = 0.05$.

11 *Statistical analysis of field data.* Results were analyzed with a three-way mixed-model
12 ANOVA with between-subjects factors (infection status and cultivar) and repeated measures on
13 one factor (year), with interactions. Post hoc contrasts followed the analysis to compare data
14 between 2012 and each of the other years (2013, 2014).

15 *Statistical analysis of screenhouse data.* Change in trunk circumference for each year
16 combination was compared with a two-factor (infection status, cultivar) analysis of variance
17 (ANOVA) with an interaction. All other screenhouse data were compared using a three-factor
18 ANOVA (infection status, cultivar, time) with two-way interactions between all factors.
19 ANOVA tests were followed by a Student's t separation of the means if warranted.

20 **Results**

21 The mean trunk cross sectional area (TCSA) of trees naturally infected with PPV in the field did
22 not differ significantly ($P > 0.05$) from that of non-infected trees at the beginning of the study
23 (data not shown). Considered for both cultivars over all three years, growth of PPV-infected

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 versus non-infected trees, as measured by annual increases in TCSA, did not differ statistically
4
5 2 ($P=0.423$) (Table 1). There was no consistent difference in growth rates for the two classes over
6
7 3 the three years. Analysis of TCSA values by cultivar showed no statistically significant
8
9 4 differences between PPV-infected and non-infected trees for any of the three years ($P>0.05$)
10
11 5 (Figure 1). Likely reflecting their younger age, the growth of PPV-infected and non-infected
12
13 6 'Brighton' trees was significantly higher over each subsequent year of study. Growth of infected
14
15 7 'Allstar' trees did not differ between years, but the yearly increase in TCSA of non-infected trees
16
17 8 was significantly higher in 2014 compared with the previous two years. Similar to the field
18
19 9 results, growth of peach trees in the greenhouse that had been inoculated with PPV did not
20
21 10 differ from that of healthy trees during the first year ($P=0.977$), second year ($P=0.183$), or over
22
23 11 all three years ($P=0.353$) of the study (Table 2).

24
25
26
27
28 12 Measurements of leaf chlorophyll that are associated with nitrogen levels provide another
29
30 13 indicator of tree vigour. PPV-infected and non-infected peaches in the commercial orchard did
31
32 14 not differ ($P=0.866$) with respect to leaf chlorophyll (SPAD meter readings) (Table 1). Infection
33
34 15 status also did not affect cold hardiness of fruit buds assessed in mid-winter in 2013 or 2014
35
36 16 ($P>0.05$); there was also no difference ($P=0.330$) between the two cultivars over both years
37
38 17 (Table 1). Regardless of virus infection, 100 % of the fruit buds of both cultivars were killed at a
39
40 18 temperature of about -19°C .

41
42
43
44 19 For both cultivars, yield efficiencies over the three years based on fruit production (kg)
45
46 20 relative to the TCSA were not significantly different ($P=0.952$) for trees infected with PPV in the
47
48 21 field compared with non-infected trees (Table 1). Mean values were similar for infected and non-
49
50 22 infected trees during the first two years. PPV-infected trees produced approximately 10% more
51
52 23 fruit relative to their trunk cross sectional areas in 2015, but the difference was not significant
53
54
55
56
57
58
59
60

R. Samara et al. Impact of *Plum pox virus* infection...

1 (P>0.05). Analysis of yield efficiencies separately for each cultivar showed no significant
2 differences (P>0.05) between PPV-infected and non-infected trees for either cultivar in any year
3 (Figure 2). The yield efficiencies of 'Brighton' and 'Allstar' trees were significantly lower
4 during 2013 compared with 2012 regardless of infection status, and both cultivars produced
5 significantly more fruit per TCSA during 2014 compared with the previous two years. In the
6 greenhouse, healthy trees produced more fruit on average (8.03 kg/tree/yr) than infected trees
7 (6.02 kg/tree/yr), but the difference was not statistically significant (P=0.89) (Table 2).

8 For both cultivars combined, trees infected with PPV in the field produced significantly
9 larger numbers of fruit (P=0.008) during the two years of assessment than the non-infected trees
10 (Table 1). However, the average fruit size and average fruit mass were significantly lower
11 (P=0.019 and P=0.035, respectively) than fruit from healthy trees (Table 1). The production of
12 more fruit of smaller size for the infected trees compared with the healthy trees accounts for a
13 lack of difference in yield efficiency between the two infection categories. Average yield varied
14 between years for both cultivars, perhaps due to environmental conditions and variation in
15 agricultural practices such as pruning and thinning. Grading of fruit into size categories
16 suggested that more fruit from PPV-infected trees sorted into the smaller grade 2 category (57-64
17 mm dia.) relative to non-infected trees, but there were no significant differences (P>0.05)
18 between infected and non-infected trees in the proportions of total fruit assorted to the seven size
19 categories (Figure 3). In the greenhouse, trees not infected with PPV produced individual fruit
20 that weighed slightly more (157.7 vs. 141.7 g; P= 0.121) on average and were larger in size (avg.
21 circumference = 34.9 vs. 32.5 cm; P=0.154) compared with fruit from trees that had been bud-
22 inoculated with PPV, but the differences were not statistically significant (Table 2).

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 At the commercially mature stage as determined by the producer, there were no
4
5 2 significant differences ($P > 0.05$) between infected and non-infected trees in the recorded fruit
6
7 3 ripeness indices (Table 1). Over each of the three years, yearly average titratable acidity (TA)
8
9 4 values for the two cultivars ranged from 6.85-8.95 g/L for PPV-infected trees and 7.07-8.88 g/L
10
11 5 for non-infected trees ($P=0.871$). Yearly average juice pH values over the course of the study
12
13 6 ranged from 3.56-3.72 for infected and from 3.51-3.67 for non-infected trees ($P=0.371$). Soluble
14
15 7 solids content (SSC) measured as °Brix ranged from 10.8-12.9% and 10.6-12.8% for fruit from
16
17 8 infected and non-infected trees, respectively ($P=0.616$). There were no consistent differences in
18
19 9 any of the measured fruit ripeness values between fruit from infected and non-infected trees over
20
21 10 the three years of study (Table 1). Measurements of fruit firmness were higher in every year for
22
23 11 fruit from non-infected trees, with values from 9.0-21.5% higher than for infected trees (Table
24
25 12 1). These yearly average values were not statistically different ($P>0.05$), however, and there was
26
27 13 also no difference in fruit firmness when all years and both cultivars were considered together
28
29 14 ($P=0.36$). Chroma and 'L' fruit colour assessments which relate to advancing fruit maturity were
30
31 15 slightly higher in every year for fruit from PPV-infected trees than for non-infected trees (Table
32
33 16 1), but the differences were not statistically significant ($P>0.05$). Analysis of the main effect of
34
35 17 infection status for cultivars and years combined showed no overall differences for Chroma
36
37 18 ($P=0.771$) or 'L' values ($P=0.076$). Differences in fruit Hue angle were not consistent across
38
39 19 years and there was no overall difference ($P=0.650$) between fruit from infected and from
40
41 20 healthy trees (Table 1).

42
43
44
45
46
47
48
49 21 Similar to the field results, fruit produced by PPV-infected trees grown in the
50
51 22 screenhouse did not differ from fruit of non-infected trees with respect to pH ($P=0.835$) or °Brix
52
53 23 values ($P=0.485$) (Table 1). For all three cultivars over both years, average pH values were

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 nearly identical and average °Brix readings only 1.5% higher for fruit from healthy trees
4
5 2 compared with fruit from trees infected with PPV. Pressure readings for infected fruit were
6
7 3 significantly lower ($P=0.023$) than for healthy fruit. Fruit Chroma values for ‘Garnet Beauty’
8
9 4 differed from the other two cultivars with respect to infection status (infection x cultivar
10
11 5 interaction) and had to be analyzed separately. While there was no significant difference
12
13 6 ($P=0.385$) in Chroma values for infected versus healthy ‘Garnet Beauty’ fruit (Table 2), infection
14
15 7 of ‘Catherina’ and ‘Baby Gold’ trees in the screenhouse resulted in significantly higher
16
17 8 ($P=0.003$) Chroma values compared to healthy trees. For cultivars and years combined, there
18
19 9 were no significant differences in ‘L’ ($P=0.116$) or Hue ($P=0.177$) readings between fruit from
20
21 10 PPV-infected versus healthy trees (Table 2).
22
23
24
25

26 11 **Discussion**

27
28 12 Most plant diseases have adverse effects on plant growth and productivity, which can range from
29
30 13 relatively minor reductions to total crop loss and death of the host plant. When PPV was first
31
32 14 discovered in North America little was known about the impact of PPV-D on crop production,
33
34 15 fruit quality, and tree vigor and hardiness. While PPV-D infection has been linked with
35
36 16 unmarketable fruit, tree mortality, and up to 100% crop loss for certain *Prunus* species, details
37
38 17 about the impact on peach production are limited (Anonymous 2013). Following the termination
39
40 18 of the Canadian eradication program in 2011, an opportunity was presented to compare the
41
42 19 impact of the Ontario isolate of PPV-D on infected peach trees with healthy trees in a
43
44 20 commercial orchard. A survey of over 11,000 peach trees during 2011-2012 in orchards in close
45
46 21 proximity to formerly heavily infected orchard blocks only identified nine PPV-positive trees for
47
48 22 use in our study. This was due in large part to the near success of the eradication program and a
49
50
51
52
53
54
55
56
57
58
59
60

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 compensation program that encouraged voluntary block removals in orchards adjacent to PPV-
4
5 2 infected blocks.

6
7 3 Viral diseases of fruit trees can often take many years before symptoms are expressed
8
9 4 throughout the canopy. Irregular movement and distribution of virus in PPV in newly infected
10
11 5 *Prunus* spp. is well documented (Dosba et al. 1986; Ferri et al. 2002; Dicenta et al. 2003).
12
13 6 Sampling and mapping of individual scaffolds and branches of the infected field study trees in
14
15 7 this study demonstrated that the canopies were uniformly infected, suggesting that the trees had
16
17 8 become infected with PPV more than one or two years previously (Sutic 1971; Wijkamp & Van
18
19 9 der Gaag 2011, Rimbald et al. 2015). Young trees usually have higher virus concentrations one
20
21 10 year post-inoculation than older trees (infected >40 yrs) (Polak 1998).
22
23
24
25

26 11 Results obtained over the three years of our field study showed few significant differences
27
28 12 between PPV-positive and negative control trees for all of the measured attributes. There was no
29
30 13 difference in vigour as expressed by comparisons of TCSA, yield efficiency, chlorophyll
31
32 14 measures, or cold hardiness of fruit buds (Table 1). Fruit at marketable maturity did not differ
33
34 15 with respect to pH, soluble solids, firmness, titratable acidity or measured colour parameters.
35
36 16 Infected trees did, however, produce larger numbers of fruit of significantly smaller size (Table
37
38 17 1).
39
40
41

42 18 Results from our screenhouse trial support those from the field. PPV-infected and healthy
43
44 19 trees did not differ with regard to growth rate, fruit production, or in most measures of fruit
45
46 20 quality or maturity (Table 2). Fruit from infected trees had lower pressure readings. Infected
47
48 21 ‘Catherina’ and ‘Baby Gold’ trees produced fruit with higher colourimeter measurements
49
50 22 (Chroma) on the fruit skin. These measures can reflect a stress response and advanced ripening.
51
52 23 This is in agreement with results from a preliminary study in 2003 demonstrating a slightly
53
54
55
56
57
58
59
60

R. Samara et al. Impact of *Plum pox virus* infection...

1
2
3 1 earlier maturation date of infected fruit of two fresh market peach cultivars, 'Redhaven' and
4
5 2 'Early Redhaven' (Errampalli et al. 2003). Additionally, taste preference tests of healthy and
6
7 3 infected fruit indicated an overall 74% preference for the infected fruit, likely influenced by
8
9 4 slightly higher sugar levels.

10
11
12 5 PPV was not detected in the screenhouse nursery trees until the year following infection,
13
14 6 with over one half of the trees testing strongly positive by the second year. Three years post-
15
16 7 inoculation, no significant differences were seen in any of the measured parameters between
17
18 8 healthy and infected trees other than some degree of advanced ripening. Visually, trees infected
19
20 9 with PPV in the field or the screenhouse were indistinguishable from healthy trees in overall
21
22 10 appearance. None of the cultivars showed flower breaking symptoms or any distinct leaf spots,
23
24 11 streaks, or deformities. Anecdotal reports from some growers implied that the infected trees
25
26 12 often appeared more vigorous and healthier.

27
28
29
30
31 13 More severe strains (PPV-M and Rec) reported infecting peach in other countries have a
32
33 14 more devastating impact on production and fruit quality (Nemeth 1994; Glasa et al. 2012). To
34
35 15 our knowledge, no other comparable impact studies were found in Europe or Chile that
36
37 16 exclusively addressed PPV-D infection in peach (Herrera, 2013). While it has been estimated
38
39 17 that yield reductions of up to 15% could occur based on European experience, supporting
40
41 18 evidence is not available (CFIA 2004). The lack of significant major differences between PPV-
42
43 19 positive and PPV-negative trees is an important finding from both field and screenhouse studies.
44
45 20 Our findings, while admittedly based on a small number of trees naturally infected in the field,
46
47 21 suggest that this mild strain of PPV-D has little measureable impact on several commercial peach
48
49 22 cultivars growing in a cool temperate climate in Ontario. Infected trees continued to produce
50
51 23 good yields of high quality fruit with no impact on tree vigor and bud hardiness in both the field
52
53
54
55
56
57
58
59
60

R. Samara et al. Impact of *Plum pox virus* infection...

1 and greenhouse studies. Based on anecdotal reports from growers over the 11 years that the
2 eradication program was in effect, despite varying degrees of symptom expression on different
3 fresh market peach cultivars and different growing conditions, they did not experience losses in
4 crop yield or increased mortality from winter kill. Long term infection by a Spanish isolate of
5 PPV-D has been shown to produce oxidative stress, and the authors suggest that an antioxidative
6 metabolism imbalance may be related to the progress of PPV infection and symptoms in peach
7 trees (Hernandez et al. 2004). It would be of interest to compare such changes in the Canadian
8 PPV-D isolate which is less aggressive, with mild to absence of symptoms on many peach
9 cultivars.

10 Our findings that the Ontario isolate of PPV-D causes minimal effects on fresh market
11 peaches does not eliminate all concern. Increasing levels of PPV-D in the industry will adversely
12 affect other susceptible and symptomatic crops such as plum and nectarine. As has happened in
13 other countries, persistence of the virus in Ontario stone fruits over time is likely to result in
14 mutations with greater pathogenicity. More severe isolates of the D strain have been described
15 (Dallot et al. 1998) often with demonstrated differences in host range and aphid vectors. This is
16 not surprising since small differences in the genetic sequence as a result of mutation can have
17 drastic effects on Potyvirus biology (Schneider et al. 2011). Further studies should also be made
18 to evaluate other peach cultivars, as well as other susceptible *Prunus* species, and include
19 investigations on the phytochemical composition of the fruit. This is important since it influences
20 their taste and quality. Co-infections of PPV with other viruses occurring in fruit trees may
21 enhance the pathogenicity. This has been shown in mixed infections of PPV and *Prune dwarf*
22 *Ilarvirus* (PDV) and *Prunus necrotic ringspot virus* (PNRSV) on some plum cultivars exhibiting
23 growth reduction, bark canker and trunk malformation and tree mortality (Nemeth 1992). The

R. Samara et al. Impact of *Plum pox virus* infection...

1 synergistic effect of PPV with other viruses has also been shown to reduce growth of seedlings
2
3 by 2.9 – 69.1% (Nemeth 1992).
4
5
6

7
8 The continued spread of a single PPV-D isolate in Niagara provides a unique opportunity
9
10 to examine both the epidemiology and impact at farm gate of this disease. More extensive
11
12 cultivar studies over a longer period under varying climatic conditions and management regimes
13
14 would benefit our understanding of this disease and potentially provide means to mitigate its
15
16 impact to the industry. The latent nature of PPV-D infections, lower virus titre and reduced
17
18 transient symptoms, as we have shown in this study, could explain why PPV-D strains have
19
20 become much more widespread globally (Schneider et al. 2011; Wang et al. 2006).
